ABSTRACT

This paper presents a generic technique for the transient nonlinear dynamic analysis (TNTA) and the static equilibrium analysis (SESA) of a turbomachine running on foil air bearings (FABs). This technique is novel in two aspects: (i) the turbomachine structural model is generic, based on uncoupled modes (rotor is flexible, non-symmetric and includes gyroscopic effects); dynamics of support structure can be accommodated; (ii) the finite-difference (FD) state equations of the air films are preserved and solved simultaneously with the state equations of the foil structures and the state equations of the turbomachine modal model, using a readily available implicit integrator (for TNTA) and a predictor-corrector approach (for SESA). An efficient analysis is possible through the extraction of the state Jacobian matrix using symbolic computing. The analysis is first applied to the finite-element model of a small commercial automotive turbocharger that currently runs on floating ring bearings (FRBs) and is slightly adapted here for FABs. The results of SESA are shown to be consistent with TNTA. The case study shows that, for certain bearing parameters, it is possible to obtain a wide speed range of stable static equilibrium operation with FABs, in contrast to the present installation with FRBs. Application of the method to a test rig reported in the literature reveals a reasonable degree of correlation between theory and experiment.

INTRODUCTION

FABs, like gas or oil bearings, are capable of introducing undesirable nonlinear effects into the dynamics of a rotor-bearing system [1-3], necessitating an efficient and reliable means for their simulation. The dynamics of FAB turbomachinery are governed by the interaction between the turbomachine, air films and foil structures. Due to the computational burden involved, the solution process has been subject to simplifications to three aspects of the problem:

- The compressible Reynolds equation (RE) governing the air film pressure distribution;
- The structural model of the turbomachine;
- The foil structure model.

This paper addresses the current simplifications to the first two aspects.

With regards to the first aspect of the problem, as discussed in [1, 2], in the case of compressible fluid bearings the RE is a state equation since it includes time as an independent variable [3-8]. The use of Finite Difference (FD)/Finite Element (FE)/Control Volume methods [3-9] to discretize the RE over the air film, creates a grid of \( N_x \times N_y \) points representing the pressure field, turning the RE into a set of \( N_x \times N_y \) first order ordinary differential equations (ODEs) with time as the independent variable (state equations) [1, 2]. Additionally, the air film gap at a given location is a function of the foil deformation there, apart from the journal displacement. Hence, a further \( n_{foil} \) state equations are introduced and the total number of state equations to be solved would be equal to \( 2H + n_y(N_x \times N_y + n_{foil}) \) where \( H \) is the number of rotor modes and casing modes (if considered), and \( n_y \) is the number of bearings [1, 2]. Such a large nonlinear system would be numerically “stiff”, requiring very small time-steps to maintain a given accuracy if an explicit numerical integration scheme is used [10]. An implicit integrator uses a larger step size for a given accuracy [10]. However, this advantage would be useless without an efficient means of calculating the required Jacobian matrix of such a large system at each time step [10]. Hence, for a realistic rotor system, the simultaneous solution of the complete system of state equations has hitherto been avoided.

In an attempt to make the integration faster, it has been common practice to adopt a non-simultaneous solution approach wherein the air-film ODEs are uncoupled from the rest and treated as algebraic rather than state equations, as in [3-8]. In such works, the air-film ODEs were approximated into a system of algebraic equations by replacing the term \( \frac{\partial q}{\partial t} \) by a backward difference approximation and approximating the current values of air film gap \( h \) and \( \frac{\partial h}{\partial t} \) using the journal and foil state variables at the previous time step \( t_{k-1} \). These resulting equations were then solved iteratively to yield the pressure distribution and, hence, the bearing forces at \( t_k \). These latter were then used in the integration of the rotor ODEs to yield the journal displacements and velocities at \( t_k \). The approximate pressure distribution at \( t_k \) was also used to update the foil deflection distribution.

Since the above-described methods do not reflect the true simultaneously coupled nature of the state variables of the original stiff system, they are inevitably slow through the need to maintain sufficiently small time steps [1, 2]. In fact, such approximations required checking either by repeated calculations for different time steps [6] or as part of an iterative feed-back loop to restore the coupling between the subsystems [8]. In previous research [1, 2], the authors developed two
alternative techniques (respectively based on FD and Galerkin Reduction) to preserve the state equations of the air films and solve them simultaneously with the other state equations. In the present paper, the state equations are similarly preserved but only FD is used and symbolic computing is used as an alternative to the vectorised formulation adopted in [1, 2] for the efficient computation of the Jacobian.

With regard to the second simplification aspect listed at the start, it is noted that most (if not all) research that considered nonlinear FABs has assumed a rigid rotor. For example, the above-mentioned works [1-8] assumed a simple symmetric rigid rotor-bearing system. Other works considered rigid rotors with four degrees of freedom (DOFs) (corresponding to rigid rotor-bearing system.  Other works considered rigid rotors with four degrees of freedom (DOFs) (corresponding to translation and rotation in each of the $x$, $y$, $z$ planes) [11] or five DOFs (where an additional axial DOF was considered to account for an air foil thrust bearing) [12].

The turbocharger and test rig considered in this paper are typically run at 120,000 rpm (2 kHz). Hence, the assumption of rotor rigidity is not appropriate. Moreover, at such high speeds, the support structure dynamics may be influential. The modal technique presented in this paper can accommodate both rotor and support structure flexibility, in a similar fashion to the approach developed by one of the authors for turbochargers on oil bearings (FRBs) [13].

**NOMENCLATURE**

\( c^{(n)} \) undeformed radial clearance of FAB $n$

\( c_o \) undeformed radial clearance of FAB in [6, 7]

\( f_{rel}^{(n)} \) vector of forces of FAB $n$, eq. (2)

\( k_{rel}^{(n)} \) air film gap divided by $c^{(n)}$

\( H \) total number of modes of linear part

\( H_{b}, H_{b}, \ldots \) modal matrices, eqs. (1), (3)

\( k_{b}, \zeta_{b} \) dimensional, non-dimensional foil stiffness of FAB $n$ used in eq. (7)

\( k_{b} \) dimensional foil stiffness of FAB in [6, 7]

\( L_{b}^{(n)} \) axial length of FAB $n$

\( n \) bearing identifier ($n = 1, 2$ in Figure 1)

\( n_{state} \) total number state variables

\( N_{x}, N_{\theta} \) number of points of FD grid along $\zeta$, $\theta$

\( p^{(n)}(\zeta, \theta) \) absolute air pressure at ($\zeta$, $\theta$) for FAB $n$

\( p_{a}, \bar{p}^{(n)} \) atmospheric pressure, $p^{(n)}/p_{a}$ resp.

\( p_{g,\theta}^{(n)} \) average gauge pressure at $\theta$, eq. (8)

\( \bar{p}_{g,\theta}^{(n)} \) vector of values of $p_{g,\theta}^{(n)}$ at discrete $\theta$ values

\( \mathbf{P} \) diagonal matrix defined by eq. (4)

\( \mathbf{q} \) vector of modal coordinates, eq. (1)

\( R^{(n)} \) undeformed radius of FAB $n$

\( \mathbf{s} \) vector of state variables, eqs. (16), (17)

\( \mathbf{s}_{E} \) static equilibrium solution of eq. (16)

\( \mathbf{u}, \mathbf{w} \) vectors of unbalance and gravity forces resp.

\( \bar{\mathbf{u}}^{(n)} \) radial foil deflection at $\theta$ divided by $c^{(n)}$

\( \bar{\mathbf{u}}^{(n)} \) vector of values of $\bar{u}^{(n)}$ at discrete $\theta$ values

\( x_{rel}^{(n)}, y_{rel}^{(n)} \) relative displacements at FAB $n$ (Figure 1(b))

\( z^{(n)} \) axial displacement from bearing mid-section = $z^{(n)}/R^{(n)}$

\( \zeta \) angular local bearing coordinate (Figure 1(b))

\( \theta \) bearing number, defined under eq. (5)

\( \Lambda_{n} \) linearization eigenvalue with highest real part

\( \eta \) damping loss factor of foil structure

\( e^{(n)} \) vector of $e_{x,y}^{(n)}$, eq. (12)

\( \Psi^{(n)} \) vector of values of $\psi^{(n)}$ at discrete $\zeta$, $\theta$ values

\( \Phi_{r}, \Phi_{x}^{(r)} \) eigenmodes of mode $r = 1 ... H$ at selected degrees of freedom (see below eq. (3))

\( \mathbf{A} \) diagonal matrix of squares of natural frequencies, eq. (1)

\( \rho^{(n)} \) right-hand of FD transformed equation (5)

\( \sigma^{(n)} \) vector function defined by eq. (14)

\( \chi \) nonlinear vector function of $\mathbf{s}$, eq. (16)

\( \tau \) non-dimensional time ($= \Omega t/2$)

\( \Omega \) rotational speed (rad/s)

\( \omega \) general frequency (rad/s)

\( \mathbf{FAB} \) Foil Air Bearing

\( \mathbf{FRB} \) Floating Ring Bearing

\( \mathbf{SESA} \) Static Equilibrium Stability Analysis

\( \mathbf{TND} \) Transient Nonlinear Dynamic Analysis

**2 COMPUTATIONAL ANALYSIS**

**2.1 State Equations**

Figure 1(a) shows a generic turbocharger assembly fitted with two FABs. Figure 1(b) shows the cross-section of FAB $n$ ($n = 1, 2$) where $J_s$, $B_s$ respectively denote the centres of the journal and bearing housing. The “linear part” of the assembly is defined as the system that remains in Figure 1(a) when the FABs are replaced by gaps i.e. the linear part comprises the uncoupled (free-free) rotor and the support structure. Let $\mathbf{q}$ be the $H \times 1$ column matrix (vector) of modal coordinates of the linear part and $\mathbf{A}$ the diagonal matrix of the squares of the natural frequencies. The equations of motion are written as:

\[
\mathbf{q} + \mathbf{Aq} = \mathbf{H}_{x}^{T}\mathbf{u} + \mathbf{H}_{w}^{T}\mathbf{w} + \mathbf{H}_{e}^{T}\mathbf{pHq} + \sum_{n=1}^{2} \mathbf{R}_{n}^{T}\mathbf{f}_{n} \tag{1}
\]

where:

\[
\mathbf{f}_{n} = [f_{x}^{(n)}, f_{y}^{(n)}]^{T} \tag{2}
\]

is the vector of $x$, $y$ forces exerted by FAB $n$ on its journal $J_s$. 

\[ H_{r_{n}} = H_{r_{n}} - H_{r_{n}} = [\Phi_{r_{n}}^{(1)} \ldots \Phi_{r_{n}}^{(H)}] - [\Phi_{r_{n}}^{(1)} \ldots \Phi_{r_{n}}^{(H)}] \tag{3} \]

\[ \Phi_{r_{n}}^{(r)} \text{, } r = 1 \ldots H, \text{ is the mass-normalised } 2 \times 1 \text{ eigenvector whose rows respectively define the } x \text{ and } y \text{ displacements of } J_{r} \text{ in mode no. } r. \text{ Similarly for } \Phi_{w_{r_{n}}}^{(r)}: H_{w} \text{ and } H_{w} \text{ are the matrices whose columns are the mass-normalised eigenvectors } \Phi_{r_{n}}^{(r)} \text{, } \Phi_{w_{r_{n}}}^{(r)} \text{ evaluated at the degrees of freedom corresponding to the directions and locations of the elements of the vector of unbalance forces } u \text{ and the vector of static loads } w. \text{ Since the rotor is statically determinate, its distributed weight could be replaced by two equivalent concentrated loads at the bearing journals.} \]

The modes in eq. (1) pertain to the linear part at zero rotor speed. The right-hand term \( H_{g}^{T} P H_{g} q \) accounts for the gyroscopic effect on the rotating nonlinear assembly. This effect is assumed to be concentrated at \( G \) points on the rotor. \( P \) is the diagonal matrix:

\[ P = \Omega \text{diag}([-I_{1}, I_{1} \ldots -I_{G}, I_{G}]) \tag{4} \]

where: \( \Omega \) is the rotational speed (rad/s), \( I_{k} \) is the polar moment of inertia at rotor location \( k (=1 \ldots G) \). \( H_{g} \) and \( H_{w} \) are the matrices whose columns are the eigenvectors \( \Phi_{g}^{(r)} \text{, } \Phi_{w}^{(r)} \) taken at the degrees of freedom corresponding to the directions and locations of the elements of the gyroscopic moment and rotation vectors \( g \text{ and } \alpha \) defined in reference [13] (the latter vector is given the symbol \( \theta \) in [13]).

For FAB \( n \) of radius \( R(n) \) and length \( L(n) \) (Figure 1(b)), let \( p^{(n)}(\xi, \theta) \) denote the distribution of the air film pressure (absolute) where \( \xi = z_{rp}^{(n)}/R(n) \). This distribution is then governed by the isothermal RE:

\[ \frac{\partial \psi^{(n)}}{\partial \tau} = \frac{1}{\Delta^{(n)}} \left( \frac{\partial}{\partial \theta} \left[ \psi^{(n)} \left( \frac{\partial \phi^{(n)}}{\partial \theta} - \frac{\partial \phi^{(n)}}{\partial \xi} \right) \right] + \frac{\partial}{\partial \xi} \left[ \psi^{(n)} \left( \frac{\phi^{(n)}}{\Delta^{(n)}} \left( \frac{\partial \phi^{(n)}}{\partial \xi} \right) \right) \right] \right) \frac{\partial \psi^{(n)}}{\partial \theta} - \frac{\partial \psi^{(n)}}{\partial \xi} \tag{5} \]

where: \( \tau = \Delta t/2 \) is non-dimensional time, the bearing number \( \Delta^{(n)} = \frac{60 \mu c^{(n)} / R^{2}}{\rho_{a}} \), \( \mu \) is the air viscosity, \( c^{(n)} \) is the radial clearance with no foil deflection, \( \psi^{(n)} = \tilde{\psi}^{(n)} \kappa^{(n)}, \tilde{\psi}^{(n)} = \frac{p^{(n)}}{\rho_{a}} \), \( p_{a} \) being the atmospheric pressure and \( \kappa^{(n)} \) the non-dimensional air-film gap at a position \( (\xi, \theta) \):

\[ \kappa^{(n)} = 1 - \kappa_{x}^{(n)} \cos \theta - \kappa_{y}^{(n)} \sin \theta + \bar{\psi}^{(n)} \tag{6} \]

In equation (6): \( \kappa_{x}^{(n)} = x_{cel}^{(n)}/c^{(n)}, \kappa_{y}^{(n)} = y_{cel}^{(n)}/c^{(n)} \) are the non-dimensional Cartesian displacements of \( J_{a} \) relative to \( B_{n} \) (Figure 1(b)) (\( B_{n} \) may be dynamic); \( \bar{\psi}^{(n)} = \frac{\psi_{rel}^{(n)}}{c^{(n)}} \) is the non-dimensional foil deflection at a position \( (\xi, \theta) \).

The foil structure used in this paper assumes that the variation of the deflection of the foil in the axial direction is negligible [14]:

\[ \frac{d \psi^{(n)}}{d \tau} = \frac{2}{\eta} \left( \frac{\bar{\psi}^{(n)}}{k_{b}} - \bar{\psi}^{(n)} \right) \tag{7} \]

where: \( \bar{\psi}^{(n)} = \psi^{(n)}(\theta) \), \( k_{b}^{(n)} = k_{b}^{(n)} c^{(n)}/\rho_{a} \) is the non-dimensional form of \( k_{b}^{(n)} \), the stiffness per unit area of the foil structure \( (N/m^{3}) \) and \( \bar{\psi}^{(n)} \) is the average of the non-dimensional gauge pressure \( \bar{\psi}_{g}^{(n)}(\xi, \theta) = \bar{\psi}^{(n)}(\xi, \theta) - 1 \) over the \( \xi \) or \( z^{(n)} \)-direction for a given \( \theta \):

\[ \bar{\psi}_{g}^{(n)} = \frac{\psi_{rel}^{(n)}}{c^{(n)}} - L_{(n)}/2R^{(n)} \int_{\psi_{rel}^{(n)}}^{\psi_{rel}^{(n)}} \left[ \psi^{(n)} - 1 \right] d\xi \tag{8} \]

As in [6, 7], the damping in the foil structure is quantified by a hysteretic loss factor \( \eta \). However, \( \eta \) is only defined for harmonic vibration [15] and its equivalent viscous damping coefficient in the time domain is \( k_{b}^{(n)} \eta /\omega \), \( \omega \) rad/s being the frequency of the vibration. Hence, with this damping model, time domain analysis for arbitrary response inevitably necessitates the use of an assumed equivalent viscous damping coefficient. In [6, 7] alternative equivalent coefficients of \( k_{b}^{(n)} \eta /\omega \) and \( k_{b}^{(n)} \eta /\omega \) were used (the \( \omega \) in the latter was prescribed). In the present work, the former option \( (k_{b}^{(n)} \eta /\omega \) is used throughout (as per equation (7)). The validity of this assumption for (self-excited) limit cycles (which have a fundamental frequency unrelated to the rotational speed, and harmonics) was tested in [2] using a frequency domain solution process (Harmonic Balance) which can accommodate the correct damping expression for each unknown frequency component. The cases studied in [2] showed that the assumption of \( k_{b}^{(n)} \eta /\omega \) in the time domain integration process had little effect on the limit cycle that the trajectory approaches in the steady-state.

The rotor equations (1) are linked to the bearing equations (5), (7) through the forces \( f_{n} \), which are obtained by integrating the air film pressure distribution in FAB \( n \):

\[ f_{n} = -p_{a} \left( R^{(n)} \right)^{2} L_{(n)}/c^{(n)} \int_{\psi_{rel}^{(n)}}^{\psi_{rel}^{(n)}} \left[ \psi^{(n)} - 1 \right] \cos \theta d\psi \tag{9} \]
Figure 1. Turbocharger assembly with FABs: (a) turbocharger schematic; (b) cross-section of FAB

The system response is obtained by solving simultaneously the three sets of equations (1), (5), (7). This can be done using readily available time domain implicit integration routines after the transformation of equations sets (5), (7) into FD format.

Since each bearing is open to atmosphere at both ends, symmetry can be exploited and the FD grid need only cover half the axial length of the bearing. The rectangular grid has \( N_x \times N_{\theta} \) points where \( \zeta = \zeta_i, \ i = 1, ..., N_z, \ \theta = \theta_j, \ j = 1, ..., N_{\theta} \). It is noted that the bearing edge, where \( \psi^{(n)} = \tilde{h}^{(n)} \), is excluded from the grid. However, this boundary condition is considered when estimating partial derivatives and integrating. Let:

\[ \psi^{(n)} = \begin{bmatrix} \psi_{i,1}^{(n)} & \ldots & \psi_{i,J}^{(n)} \end{bmatrix}^T (N_x N_{\theta} \times 1) \]

(10)

\[ \tilde{w}^{(n)} = \begin{bmatrix} \tilde{w}_{j,1}^{(n)} & \ldots & \tilde{w}_{j,K}^{(n)} \end{bmatrix}^T (N_{\theta} \times 1) \]

(11)

\[ e^{(n)} = \begin{bmatrix} e_{x}^{(n)} & e_{y}^{(n)} \end{bmatrix}^T \]

(12)

where \( \psi_{i,j}^{(n)} = \psi^{(n)}(\zeta_i, \theta_j), \tilde{w}_{j}^{(n)} = \tilde{w}^{(n)}(\theta_j) \) and

\[ e^{(n)} = e^{(n)}(q) = H_i(q)/c^{(n)} \]

(13)

Using central-difference formulae [16, 17] to approximate the partial derivatives in eq. (5), this equation can be transformed into a set of state equations whose right hand side is denoted by a vector \( \rho^{(n)} \). Let \( \tilde{p}^{(n)}_\phi \) denote the vector of pressures \( \tilde{p}^{(n)}_\phi(\theta_j) \) computed from the discrete form of equation (8) and let the discretised right hand side of equation (7) be denoted as:

\[ \sigma^{(n)} = \frac{1}{\eta} \left\{ \sum_{n=1}^{N_{\theta}} \tilde{H}_n^{(n)} f_n \left( \psi^{(n)}, \tilde{w}^{(n)}, e^{(n)}(q) \right) \right\} \]

(14)

Both \( \rho^{(n)} \) and \( \sigma^{(n)} \) are nonlinear functions of \( \psi^{(n)}, \tilde{w}^{(n)}, e^{(n)}(q) \). Hence, the state equations of the complete assembly can be written as:

\[ \psi^{(1)}(\tau) = \rho^{(1)}(\psi^{(1)}, \tilde{w}^{(1)}, e^{(1)}(q)) \]

(15a)

\[ \tilde{w}^{(2)}(\tau) = \sigma^{(1)}(\psi^{(1)}, \tilde{w}^{(1)}, e^{(1)}(q)) \]

(15b)

\[ \psi^{(2)}(\tau) = \rho^{(2)}(\psi^{(2)}, \tilde{w}^{(2)}, e^{(2)}(q)) \]

(15c)

\[ \tilde{w}^{(2)}(\tau) = \sigma^{(2)}(\psi^{(2)}, \tilde{w}^{(2)}, e^{(2)}(q)) \]

(15d)

\[ \psi^{(1)}(\tau) = \rho^{(1)}(\psi^{(1)}, \tilde{w}^{(1)}, e^{(1)}(q)) \]

(15e)

2.2 Transient Nonlinear Dynamic Analysis (TNDA)

The system in equation (15) is in the general form required by Matlab integrator routines [10]:

\[ s' = \chi(t,s) \]

(16)

where the state vector

\[ s = \begin{bmatrix} \psi^{(1)^T} & \tilde{w}^{(1)^T} & \psi^{(2)^T} & \tilde{w}^{(2)^T} & q^T & q^T \end{bmatrix}^T \]

(17)

is \( n_{\text{state}} = 2(N_x N_{\theta} + N_{\theta}) + 2H \) elements long. In view of the numerical stiffness of the systems, the implicit integrator function ode23s was used [10]. This is based on the Modified-Rosenbrock algorithm and has adaptive time-step control to maintain the numerical error with a prescribed tolerance. As
discussed in the Introduction, it is only possible to take advantage of this function (and other stiff solvers in the Matlab ode suite), if a user-written function for the rapid computation of the Jacobian matrix \( \frac{\partial f_n}{\partial s} \) at each time-step can be provided. An analysis of the Jacobian expression reveals that the computational burden lies in the calculation of the following submatrices:

\[
\frac{\partial \mathbf{P}^{(n)} T}{\partial \mathbf{P}^{(n)} T} \mathbf{W}^{(n)} T, \\
\frac{\partial f_n}{\partial \mathbf{P}^{(n)} T} \mathbf{W}^{(n)} T.
\]

Expressions for the above matrices could be obtained using one of two alternative methods: (i) using Matlab-style vectorized formulation that minimises matrix multiplication [2]; (ii) using symbolic computing. The latter approach was used for this research. Code was developed to generate symbolic expressions for the elements in the above matrices in terms of the elements in \( \mathbf{P}^{(n)}, \mathbf{W}^{(n)}, \mathbf{c}^{(n)} \) (using Matlab Symbolic Toolbox™) and then to write these expressions into a subroutine.

2.3 Static Equilibrium Stability Analysis (SESA)

With reference to eq. (16), the static equilibrium condition at a given rotational speed can be obtained directly by finding the solution \( \mathbf{s} = \mathbf{s}^* \) of the system of nonlinear algebraic equations

\[
\chi(t, \mathbf{s})|_{t=0} = 0,
\]

whose left hand side is a nonlinear vector function of \( \mathbf{s} \) only (since \( u \) is omitted). The stability of small perturbations \( \Delta \mathbf{s} \) about \( \mathbf{s} = \mathbf{s}^* \) is governed by the linear relation

\[
(\Delta \mathbf{s})^{(0)} = \mathbf{G} \Delta \mathbf{c}^{(0)}.
\]

The solution of this linearized system is given by \( \Delta \mathbf{s} = \sum_{k=1}^{n_{\text{state}}} \mathbf{G}_k \mathbf{v}_k e^{\lambda_k t} \) where \( \lambda_k, \mathbf{v}_k \) are the eigenvalues of the Jacobian matrix \( \frac{\partial \mathbf{G}}{\partial \mathbf{s}|_{\mathbf{s} = \mathbf{s}^*}} \) and \( \mathbf{v}_k \), \( \mathbf{G}_k \) are eigenvectors and arbitrary constants respectively. Hence, the stability of the static equilibrium \( \mathbf{s} = \mathbf{s}^* \) can be investigated by examining the leading eigenvalue \( \lambda_L \) (i.e. the one whose real part is nearest to \(+\infty\)): \( \text{Re}[\lambda_L] \) is the growth factor of the dominant component of the perturbation and \( 10\% \) is the ratio of its frequency to the rotational speed. The system \( \chi(t, \mathbf{s})|_{t=0} = 0 \) was solved over a range of speeds using a predictor-corrector continuation scheme [18]. In this process the initial approximation ("predictor") to \( \mathbf{s}^* \) at the current speed was obtained from the solution at the previous speed and the damped Newton-Raphson Method ("corrector") was used to converge it to \( \mathbf{s}^* \). The predictor at the first speed in each test was supplied by industry (Figure 2(a)). This model was used to converge it to the initial approximation ('predictor') to \( \mathbf{s}^* \) using a predictor-corrector continuation scheme [18]. In this section the analysis is applied to a small commercial automotive turbocharger rotor whose finite element (FE) model was supplied by industry (Figure 2(a)). This model was somewhat similar to that used in the FRB analysis in [19]: the turbine (shaded) was integral with the shaft (i.e. one material code used), with discs added to correct the diametral and polar moments of inertia; the aluminium compressor was modeled as discs added to the steel shaft, correcting both the mass and the moments of inertia. It is also noted that the simple two-disc/flexible shaft rotor model used in the FRB analysis in [13] is approximately dynamically equivalent to the present one. Since the supplied rotor model was used on FRBs, the shaft diameter at each of the bearing locations was increased from 11mm to 20mm over a 20mm length of shaft in order to accommodate the realistically-sized FABs used in the present analysis, as indicated in Figure 2(a). This alteration resulted in increases of \( \pm \)11% in the weight of the rotor and \( \pm \)20% in the first two flexural free-free rotor modes. Figure 2(b) shows the first four free-free undamped modes of the modified rotor in one plane at zero rotational speed. These comprise: two rigid body modes (0 Hz) respectively describing translation and rotation about the mass centre; two flexural modes (1.2 kHz, 3.0 kHz). The next highest flexural mode occurred at 6.1 kHz and hence was considered not to be influential within the operating speed range of the present analysis (0-3000 rev/s), which focuses on self-excited vibration, in which sub-synchronous frequency components dominate. Also, the support structure was taken to be rigid. Hence, in the above nonlinear analysis, \( H = 8 \) (i.e. 4 free-free rotor modes for each of the \( x, y, z \) planes) and \( \mathbf{G}^{(0,\ldots,0)} = \mathbf{0} \). It is noted that, if the support structure modal properties were known and influential, then this would be simply accommodated by adding further columns to \( \mathbf{H}_n \) (eq. (3)) for which \( \mathbf{G}^{(0, \ldots, 0)} = \mathbf{0} \) and \( \mathbf{G}^{(0, \ldots, 0)} \neq \mathbf{0} \). The gyroscopic effect was disretised at the locations shown in Figure 2(b) as discs with the following polar moments of inertia (\( \times 10^{3} \) kgm², from left to right): 0.011, 0.028, 0.066, 0.329, 0.211, 0.372, 0.254, 0.137, 0.020.

Table 1. FAB length, radial clearance and foil stiffness for different simulation tests (the radii of both bearings are 10 mm for all tests; \( c_o = 32 \times 10^{-6} \text{m} \); \( k_{bo} = 4.739 \text{ GN/m}^3 \))

</table>

The radii \( R^{(1)}, R^{(2)} \) of the FABs used in the analysis were both 10 mm. The other FAB parameters were adjusted as shown in Table 1 with reference to \( R^{(n)}, c_o \) and \( k_{bo} \) where \( c_o = 32 \times 10^{-6} \text{m} \) and \( k_{bo} = 4.739 \text{ GN/m}^3 \) are, respectively, the radial clearance and foil stiffness of the larger standard FAB used in [6, 7] (which had a radius of 19.05 mm and length of 38.1 mm).
In all simulations, \( p_a = 101325 \text{ Pa}, \mu = 1.95 \times 10^{-5} \text{ Ns/m}^2 \) and foil structure loss factor \( \eta = 0.25 \) [6, 7]. The analysis in this paper focuses on self-excited instabilities and so, no rotor unbalance was considered.

The FD grid used for each FAB was \( N_x = 7, N_y = 72 \) (i.e. the full extent of each FAB was covered by a \( 15 \times 73 \) grid). This means that the number of state equations \( (15) \) was 1168. All simulations were implemented in Matlab on a standard laptop computer with Intel® Core™ i7 Processor.

Figure 2. Turbocharger rotor: (a) rotor finite element model; (b) free-free rotor modes at zero rotor speed

Figure 3 shows the simulation of the trajectory (TNDA) of the journal centres \( (J_1, J_2) \) of the two bearings from default initial conditions (corresponding to centralized journals with zero velocities, air films at atmospheric pressure and undeformed clearance).
foils) over 20 shaft revolutions at a very low speed (5×10³ rpm) for Test 1 parameters (Table 1). Both trajectories converge to a (stable) static equilibrium point; the equilibrium position of J₂ is situated at a lower position in the clearance than that of J₁ since J₂ supports a considerably larger static load (4.7N vs 1.4N - it is much closer to the centre of gravity G, see Figure 2(b)). Figure 3 also shows the predicted steady-state deformation of the clearance (i.e. the profile of the top foil) of FAB1, FAB2.

The steady-state TNDA solution to equation (15) (which, in the case above (Figure 3), is a constant state vector \( \mathbf{s}_E \)) was used as an initial approximation to the SESA process described in section 2.3 to directly compute the equilibria \( \mathbf{s}_E \) and their stability over the operating speed range. The same procedure was performed for other test parameters (Table 1). It is noted that, if the SESA process was progressed backward (rather than forward) from the starting speed of 5×10³ rpm to a very low speed, the computed equilibria \( \mathbf{s}_E \) approach the static equilibrium condition at null rotor speed (i.e. journals resting at the bottom of a deformed clearance under the rotor weight). If such an equilibrium \( \mathbf{s}_E \) were used as the initial condition for the TNDA analysis at 5×10³ rpm, instead of that marked in Figure 3, the journal centre and foil deformation would arrive at exactly the same steady-state condition. This is to be expected since, in a dissipative nonlinear system, the choice of the initial conditions of the TNDA normally has no effect on the steady-state condition. The default initial condition used in Figure 3 is very convenient since it corresponds to zero foil deflection and atmospheric pressure (i.e. does not require the prescription of an assumed deformed profile and pressure distribution).

Figures 4(a,b) show the real and imaginary parts of the leading eigenvalue \( \lambda_L \) over a speed range of 5×10³-200×10³ rpm for the SESA of Tests 1-3. The Test 1 stability plot in Figure 4(a) shows that the static equilibrium configuration is stable at A (5×10³ rpm – in agreement with the TNDA of Figure 3) but becomes unstable as the speed is increased slightly to 6×10³ rpm (point B). Hence, there is a Hopf bifurcation (marking the birth of a limit cycle [1, 18]) at point H (where Re\( \{\lambda_L\} = 0 \)).
changes (see definition of $\lambda_L$ in Nomenclature): in fact, the
shifts in Figure 4(b) coincide with kinks in Figure 4(a)).

Figure 7 shows the frequency spectra of the Test 1 limit cycles (FAB 1, $y$ direction) at $6 \times 10^3$ rpm, $100 \times 10^3$ rpm. It is seen that their fundamental frequency to rotational speed ratios are respectively 0.49, 0.26 (the non-dimensional frequency resolution of the spectrum being 0.005). It is observed that these whirl frequency ratios are quite close to the ratios 0.46, 0.22 given by the Test 1 curve in Figure 4(b) at the same speeds, despite the fact that (as seen from Figures 5, 6) the limit cycles (for which Figure 7 applies) are considerably removed from the perturbation in the immediate vicinity of the unstable static equilibrium (for which Figure 4(b) applies). It is seen that, at low speed, the instability loosely corresponds to a case
of ‘half-frequency whirl’ (as far as the fundamental frequency to speed ratio is concerned); as the speed increases, the whirl frequency appears to approach a limiting value of between a tenth and a fifth of the rotational speed (Figure 4(b)).

The Test 1-3 results in Figure 4(a) show that, increasing the L/R ratio to 2 tends to reduce the degree of instability (the perturbation growth factor) in the second half of the speed range, which is the typical operating range for this turbocharger. Hence, the L/R ratio was maintained at 2 in the subsequent tests. Figure 8 shows the stability plots for Tests 3-5 (decreasing foil stiffness at a constant radial clearance of 0.25c₀) and Tests 6-8 (decreasing foil stiffness at constant radial clearance of 0.1c₀). It is seen that, decreasing foil stiffness tends to reduce the growth factor. Comparing the Tests 3-5 plots with the Tests 6-8 plots, it is seen that, by reducing the clearance from 0.25c₀ to 0.1c₀, stability is achieved beyond 60×10⁸ rpm for a foil stiffness of kₙ₀ and beyond around 40×10⁸ rpm for a foil stiffness of 0.5kₙ₀. The stability regime was confirmed by time transient integration at specific speeds from initial conditions corresponding to a 20% perturbation in the q-subvector of the corresponding static equilibrium solution. As can be seen from the example in Figure 9, despite the sizeable initial perturbation, the journal centres J₁, J₂ settle back to their static equilibrium positions. Figure 9(b) also shows that, despite the larger static offset of J₂ (from the bearing centre), J₂ is still approximately centralized within the deformed clearance boundary. It is also noted that the SESA results showed that the static condition depicted Figure 9 is virtually invariant over the entire speed range.

4 APPLICATION TO EXPERIMENTAL RIG

In order to validate the technique presented, it was applied to the high-speed FAB test rig developed by Heshmat [21] (Figure 10). For the rotor-bearing stability tests, the central bearing and loading device were removed [21]. Hence, the generic rotor – two FAB scheme developed above is directly applicable. The experimental results in [21] revealed virtually pure self-excited vibration, with negligible influence from the rotational unbalance. This is evident from Figure 11, which shows a waterfall plot of the vibration frequency spectra obtained as the test rig was coasted down from its top speed of 2200 rev/s (132,000 rpm). It is noted that, in spite of this, Heshmat stated in [21] that there was “smooth operation without evidence of instability…” The semantics of this claim were subsequently corrected by D. W. Childs in the ensuing discussion [21], who stated that the results show that “the rotor is linearly unstable due to hydrodynamic action of the bearing from a fairly low speed up to the rotor’s peak operating speed”. It is also noted that no comparative theoretical analysis was performed in [21]. The theoretical analysis by Peng and Khonsari [14] referred to data from [21] but only focused on load-carrying capacity.

In the present paper, the rotor of Figure 10 was modeled as a uniform shaft of length 211 mm and diameter 35 mm, with a Young Modulus of 200 GN/m². It is noted that a small fraction of the quoted length in Figure 10 was taken up by the air turbine; however this was integral with the shaft and had practically the same diameter (38 mm). Hence, the turbine was ignored and the density of the shaft taken to be 7811 kg/m³, giving the quoted rotor mass of 1.545 kg. The mid-sections of FABs 1, 2 were estimated to be 27.5 mm and 36.5 mm from the respective adjacent ends of the rotor. The rotor was processed for its free-free modal properties in the same way as in Section 3, taking 4 modes in each plane, similar to those in Figure 2(b) – the flexure modes in the present case were found to be 3.36
kHz (also mentioned in [21] and noted in Figure 13(b) below) and 8.38 kHz. The equivalent static loads at FABs 1,2 were 7.11, 8.04 N respectively. The gyroscopic effect was discretised at 3 locations. From [21]: $c^{(1,2)} = 40 \times 10^{-6}$m, $R^{(1,2)} = 17.5 \times 10^{-2}$m, $L^{(1,2)} = 31 \times 10^{-2}$m. The dimensions of the bump foil were obtained from [21] and Table 3 of [14]. Using the compliance formula in [14], a Young Modulus of 212.4 GN/m$^2$ (Inconel X-750), and a Poisson Ratio of 0.3, it was calculated that $k_b^{(1,2)} = 7.89$ GN/m$^3$. The loss factor $\eta$ was assumed to be 0.25, as in Section 3. The air viscosity and FD grid size were the same as in Section 3. As in [14], centrifugal and thermal growth were not considered.

Figures 12(a,b) show the SESA results, which are presented in a way that is directly comparable to the coast down data of Figure 11. The perturbation growth factor graph (Figure 12(a)) shows that the static equilibrium configuration is indeed unstable over the entire operating range, except for very low speeds (below ~140 rev/s (8400 rpm)). Figure 12(b) shows that the dominant perturbation frequency decreases with decreasing speed, just like the measured limit cycle frequency in Figure 11. The predicted dominant perturbation frequency at the top speed of 2200 rev/s is 291 Hz, which is around 17% different from the measured limit cycle frequency (350 Hz) at the same speed. It is noted that doubling the loss factor or foil stiffness had little effect on the predicted results in Figure 12. The results were found to be moderately sensitive to the radial clearance e.g. reducing this from 40$\mu$m to 33$\mu$m raised the dominant perturbation frequency at 2200 rev/s from 291 Hz to 347 Hz. It is noted that, unlike the prediction in Figure 12(b), the limit cycle frequency in Figure 11 does not appear to asymptote towards the ‘half-frequency whirl’ condition at very low speeds. This may be due to the fact that, with the exception of the top speed, the power spectra in Figure 11 were obtained during coast down rather than at constant individual speeds [21].

When TNDA was applied at a constant speed of 2200 rev/s from initial conditions corresponding to 1% perturbed static equilibrium configuration (at that speed), the FAB journal trajectories evolved in a manner similar to Figure 6, eventually settling down to a limit cycle. Figure 13(a) shows the predicted power spectrum of the limit cycle at FAB 2. As noted previously for a different case, it is seen that the limit cycle’s fundamental frequency (374 Hz) is higher than the perturbation
frequency (291 Hz). It is also much closer to the measured limit cycle frequency (350 Hz, Figure 13(b)). The satisfactory agreement between the predicted and measured spectra in Figures 12(a,b) is moderated by the discrepancy in amplitudes, the predicted amplitude being around 5 times the measurement. However, this should come as no surprise since Coulomb damping within the foil is highly influential on the limit cycle size, as emphasized by Childs in the post-paper discussion [21]. The foil damping model used here is a simple linear one.

5. CONCLUSIONS

The research in this paper has presented a technique for the TNDA and SESA of a generic turbomachine running on FABs. The FD state equations of the two air films were preserved and solved simultaneously with the state equations of the foil structures and the state equations of the modal model of the turbomachine. The method was first applied to an actual turbocharger rotor currently running on two oil FRBs that was slightly modified to run on two FABs instead. The results of the SESA were shown to be perfectly consistent with those from the TNDA. For certain FAB parameters, limit cycles were observed over a wide speed range, and the ratio of their fundamental frequency to the rotational speed reduced from around 0.5 to a lower order as the speed was increased. This case study showed that stability of the static equilibrium configuration was promoted by increasing the FAB length-to-radius ratio, increasing the foil structure compliance and reducing the undeformed radial clearance. With the right parameters, stability was achievable over a wide operating range, in contrast to the current installation (FRBs), albeit with altered journal diameters. The technique was validated by applying it to a test rig reported in the literature. The study showed a reasonable degree of correlation between theory and experiment, particularly with regard to subsynchronous frequency prediction. However, it also flagged the need for an improved foil damping model for more accurate estimation of the limit cycle amplitude.
